Abstract

Mycosis fungoides, also known as granuloma fungoides or Alibert-Bazin syndrome, is the most common form of primary cutaneous T-cell lymphoma. In the early course of the disease, the skin lesions have significant overlap with many other primary cutaneous disorders like psoriasis, eczema, and tinea infections. Hence, early suspicion, prompt diagnosis by histopathological and immunohistochemical analysis, and regular follow-up are of utmost importance. Here we present a trilogy of cases of mycosis fungoides with varied skin lesions.

Keywords: Cutaneous lesions- Histopathology- Immunohistochemistry- Mycosis fungoides

Introduction

Mycosis fungoides (MF) is a rare entity under Extranodal Non-Hodgkin lymphoma that accounts for 50% of primary cutaneous T-cell lymphoma [1]. First described by French dermatologist Jean-Louis-Marc Alibert, the name arises from the mushroom-shaped fungus shape of the tumour on the skin surface [2]. Mostly seen in the elderly, with a male predominance. Risk factors include smoking, obesity, and certain occupations (petrochemical, textile, and metal industries) [3]. The prevalence of MF is around 5.2 per 100,000 in the western world and is more rare in India [4]. The early course of the disease can manifest as a skin rash, nodules, patches, or plaque-like lesions masquerading as dermatitis, eczema, or psoriasis, thereby leading to a delay in diagnosis, optimal treatment, and the overall life expectancy of the patient [5]. Here we present a trilogy of cases, all with varied skin manifestations, and summarise our approach to diagnosis and treatment.

Case presentations

Case 1

A 52-year-old male presented with progressive hyperpigmented nodules over the face for the last 8 months. The lesions were not associated with any pain, itching, ulcers, sinus, or discharge. There was no lymphadenopathy or hepatosplenomegaly.

Examination showed multiple nodular acneform lesions with diffuse hyperpigmentation all over the face, the largest measuring 1.1 cm by 0.75 cm (Figure 1). The patient was previously prescribed benzoyl peroxide gel along with clindamycin gel, but without any symptomatic relief with anti-acne medications, a skin biopsy was done, which revealed atypical lymphocytes around the basal layer of epidermis (epidermotropism), which were small to medium type with occasional cells showing cerebriform nuclei. Immunohistochemistry showed cells positive for CD3, CD4, and CD7 and negative for CD2, CD5, CD8, and CD30, with a Mib1 labelling index of 20%. PET CT of the whole body was within normal limits. ISCL and EORTC staging was 1A (T1N0M0B0), and the patient was initiated on psoralen with ultraviolet A (PUVA) therapy of 2.5 J/cm² twice weekly as an induction with gradual resolution of symptoms.

**Case 2**
A 45-year-old female presented with multiple erythematous annular skin lesions over the flexor aspect of face, anterior neck, both forearms, anterior abdomen, and both thigh for the last 3 years. The lesions were associated with itching but without any pain, ulcer, sinus, or discharge. Local examination showed multiple itchy, scaly plaque-like lesions on the erythematous base, the largest one on the anterior abdominal wall measuring 12 cm by 8.5 cm. A general examination revealed a BMI of 34 kg/m² along with bilateral axillary and inguinal lymphadenopathy.

A complete blood count revealed haemoglobin of 11.1 g/dl, a total leukocyte count of 8300/cumm with neutrophil predominance, and a platelet count of 3 lakhs/cu mm. Renal and liver function tests were within normal limits. Although the lesions resembled psoriasis, in view of concomitant axillary lymphadenopathy, a skin biopsy was done, which revealed the superficial dermis infiltrated by sheets of atypical lymphocytes. The individual cells had moderately pleomorphic convoluted nuclei, fine chromatin, conspicuous nucleoli, and a moderate to scanty amount of cytoplasm. Epidermotropism was present with infiltrate reaching the dermo-epidermal junction, along with pautrier abscesses, which were suggestive of mycosis fungoides (Figure 2). Immunohistochemistry showed cells positive for CD3, CD30, and CD4 and negative for CD2, CD5, and CD7, with a Mib1 labelling index of 40%. PET CT of the whole body revealed metabolically active lymphadenopathy in bilateral axillary (SUV max 4.5) and inguinal regions (SUV max 7). A bone marrow examination revealed normocellular marrow with trilineage hematopoiesis without any infiltration by atypical lymphoid cells. ISCL/EORTC staging [6] was IIB (T3N2M0B0), and the patient was initiated on psoralen with ultraviolet A (PUVA) therapy (4 J/cm²) twice weekly along with topical clobetasol cream and two cycles CVP (cyclophosphamide, vincristine, prednisolone) chemotherapy as induction with gradual resolution of symptoms after 2 cycles.

**Figure 2.** A Skin Biopsy of a 45-year-old Female Presented with Multiple Erythematous Annular Skin Lesions Showing 2. A) LOW POWER: Superficial dermis infiltrated by sheets of atypical lymphocytes (epidermotropism) along with pautrier abscesses 2.B) HIGH POWER: The individual cells had moderately pleomorphic convoluted nuclei, fine chromatin, conspicuous nucleoli, and a moderate to scanty amount of cytoplasm.

**Case 3**
A 58-year-old male presented with a progressive erythematous annular itchy skin lesion over the anterior aspect of the abdomen for the last 2 years. He had been a chronic smoker for the last 15 years, with a history of off-the-counter betamethasone use in view of dermatitis but without any relief. Local examination showed a large erythematous annular plaque measuring 12 cm by 8.5 cm on the anterior abdominal wall. There was no lesion in any other part of the body, lymphadenopathy or organomegaly.

A complete blood count revealed haemoglobin of 13.2 g/dl, a total leukocyte count of 5560/cumm with neutrophil predominance, and a platelet count of 2.5 lakhs/cu mm. Renal and liver function tests were within normal limits. A skin biopsy was done in view of the progressive lesion without any relief with anti-eczema therapy. Histopathological examination showed atypical lymphocytes invading the epidermis (epidermotropism), dermis, and cutis without spongiosis. There were occasional cells with cerebriform nuclei along with focal pautrier micro-abscesses suggestive of mycosis fungoides (Figure 2). Immunohistochemistry showed cells positive for CD3, CD4, CD5, and CD20 and negative for CD2, CD7, and CD30 with MIB1 10%. PET CT of the whole body showed no metabolically active disease. ISCL and EORTC staging was 1A (T1N0M0B0), and the patient was initiated on psoralen with ultraviolet A (PUVA) therapy (3 J/cm²) twice weekly as induction, with complete disappearance of the lesion after 12 sessions (Figures 3.A and 3.B).

**Discussion**

Cutaneous T-cell lymphomas are the second most common form of Extranodal Non-Hodgkin lymphoma, of which mycosis fungoides is the most common form. It is a rare form of Non-Hodgkin lymphoma, accounting for less than 1% of cases [7]. It originates from peripheral epidermotropic memory T-cells (CD45RO+) expressing T-cell receptors (TCR) and CD4+.

Incidence increases with age, and the median age lies
variants include folliculotropic type and granulomatous CD30 is negative in earlier stages of disease. WHO clinical neoplasm. The Mib1 labelling index is usually low, and is negative, thus differentiating it from gamma delta T-cell eczema or psoriasis. TCR beta is positive, whereas gamma differentiates it from inflammatory disorders such as eczema or psoriasis. CD3, CD4, with a lack of CD2, CD5, and/or CD7 and/or CD8 expression differentiates MF from inflammatory disorders such as eczema or psoriasis. CD3, CD4 with a lack of CD2, CD5, and/or CD7, CD8 expression differentiates MF from inflammatory disorders such as eczema or psoriasis. PUVA remains the mainstay of therapy for localised skin lesions and has an excellent prognosis when initiated early. The addition of low-dose methotrexate improves outcomes with more extensive lesions.

A definite diagnosis is made by skin biopsy. Histopathological examination shows band-like small to medium-sized atypical lymphoid infiltrates in the epidermis (epidermotropism), typically in the basal layer, often as haloed cells. Characteristic cells with cerebriform nuclei and intraepidermal collections (Pautrier’s microabscess) are only seen in a few cases [13]. Immunohistochemistry shows cells positive for CD3, CD4 with a lack of CD2, CD5, and/or CD7 and CD8 expression, which is highly specific for MF and differentiates it from inflammatory disorders such as eczema or psoriasis. TCR beta is positive, whereas gamma is negative, thus differentiating it from gamma delta T-cell neoplasm. The Mib1 labelling index is usually low, and CD30 is negative in earlier stages of disease. WHO clinical variants include folliculotropic type and granulomatous slant skin types, which show CD4 positivity, and pagetoid reticulosis type with CD8 positivity [14]. Staging is done as per ICSL and EORTIC criteria [6].

Treatment of limited-stage disease (stage IIA or below) includes topical therapy (steroids, nitrogen mustards), PUVA therapy, or local radiation. More extensive lesions usually require low-dose chemotherapy (methotrexate, retinoids, interferon, or histone deacetylase inhibitors) in adjunct with total skin electron beam therapy. Advanced-stage disease usually requires a combination of skin-directed therapies, systemic chemotherapy (CHOP, CHOEP, and CVP), and chemoimmunotherapy (alexatumumab, mogamulizumab, and brentuximab) [15]. Cases 1 and 3 were localised diseases, hence treated with PUVA therapy only, and CVP chemotherapy was added in case 2 in view of extensive skin lesions. All three cases showed excellent responses.

The prognosis of MF patients declines with age, with a 95% 10-year survival rate for early-stage disease and only 3–4 years for advanced disease; hence, early diagnosis is of utmost importance [16].

In conclusion, Mycosis fungoides, a form of cutaneous T-cell lymphoma, is a rare malignant skin condition. Early diagnosis is difficult as early forms have significant overlap with common skin conditions. Hence, regular follow-up along with a skin biopsy is of utmost importance for a timely diagnosis. Immunohistochemical evidence of cells positive for CD3, CD4 with a lack of CD2, CD5, and/or CD7, CD8 expression differentiates MF from inflammatory disorders such as eczema or psoriasis. PUVA remains the mainstay of therapy for localised skin lesions and has an excellent prognosis when initiated early. The addition of low-dose methotrexate improves outcomes with more extensive lesions.

Aknowledgements

I would like to thank my parents Suchitra Roy and Jiban Krishna Roy for their constant support, my professor Dr. Prakas Kumar Mandal for his guidance. This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Conflicts of interest

The authors declare no conflict of interest.
